# Deadlock Avoidance

- Carefully allocates (non-sharable) resources
  - The deadlock-avoidance algorithm dynamically examines the *resource-allocation state* to ensure that there can never be a *circular-wait condition*, i.e., in a safe state

# Information Known A Priori

- Requires that the system has some additional ***a priori*** information available
  - Simplest and most useful model requires that each process declare the ***maximum number*** of resources of each type that it may need

# Resource-Allocation State

- Resources available (the numbers of instances of and the types of resources available)
- Resource allocated (the numbers of instances of and the types of resources allocated)
- Maximum demands (the number of instances of and types) of resources of the threads

# Define Safe State

- System is in **safe state** if there exists a sequence  $\langle P_1, P_2, \dots, P_n \rangle$  of ALL the processes in the systems such that for each  $P_i$ , the resources that  $P_i$  can still request can be satisfied by currently available resources + resources held by all the  $P_j$ , with  $j < i$

# Define Safe State: Scenarios

- That is:
  - If  $P_i$  resource needs are not immediately available, then  $P_i$  can wait until all  $P_j$  have finished
  - When  $P_j$  is finished,  $P_i$  can obtain needed resources, execute, return allocated resources, and terminate
  - When  $P_i$  terminates,  $P_{i+1}$  can obtain its needed resources, and so on

# Resource Trajectory

- [Figure 6-8 in Tanenbaum & Bos, 2014]

# Safe and Unsafe State

- Safe state
  - The system can allocate resources to each process in some order and still avoid a deadlock
  - A safe state is not a deadlocked state
- Unsafe state
  - A deadlocked state is an unsafe state
  - An unsafe state may not be a deadlock state
  - An unsafe state is a state that may lead to a deadlock

# Safe State: Example

- A resources has 10 instances
- Does exist a scheduling order of processes A, B, C, and allow all of them to complete?
  - Notations:
    - Free: available resources; Has: resources allocated; Max: maximum demand
  - The following resource allocation sequence shows that (a) is safe

	Has	Max
A	3	9
B	2	4
C	2	7

Free: 3  
(a)

	Has	Max
A	3	9
B	4	4
C	2	7

Free: 1  
(b)

	Has	Max
A	3	9
B	0	–
C	2	7

Free: 5  
(c)

	Has	Max
A	3	9
B	0	–
C	7	7

Free: 0  
(d)

	Has	Max
A	3	9
B	0	–
C	0	–

Free: 7  
(e)

# Unsafe State: Example

- A resources has 10 instances
- Does exist a scheduling order of processes A, B, C, and allow all of them to complete?
  - (b) is unsafe: you can run B to completion, but no sufficient resources for A or C to complete

	Has	Max
A	4	9
B	2	4
C	2	7

Free: 2

(b)

	Has	Max
A	4	9
B	4	4
C	2	7

Free: 0

(c)

	Has	Max
A	4	9
B	—	—
C	2	7

Free: 4

(d)

# Safe State and Deadlocks

- If a system is in safe state  $\Rightarrow$  no deadlocks
- If a system is in unsafe state  $\Rightarrow$  possibility of deadlock
- Avoidance  $\Rightarrow$  ensure that a system will never enter an unsafe state.

# Safe, Unsafe, Deadlock State

# Deadlock Avoidance Algorithms

- If the system enters an unsafe state when the system grants the resource request
- **Single** instance of a resource type
  - Use a resource-allocation graph
- **Multiple** instances of a resource type
  - Use the Banker's Algorithm

# Questions?

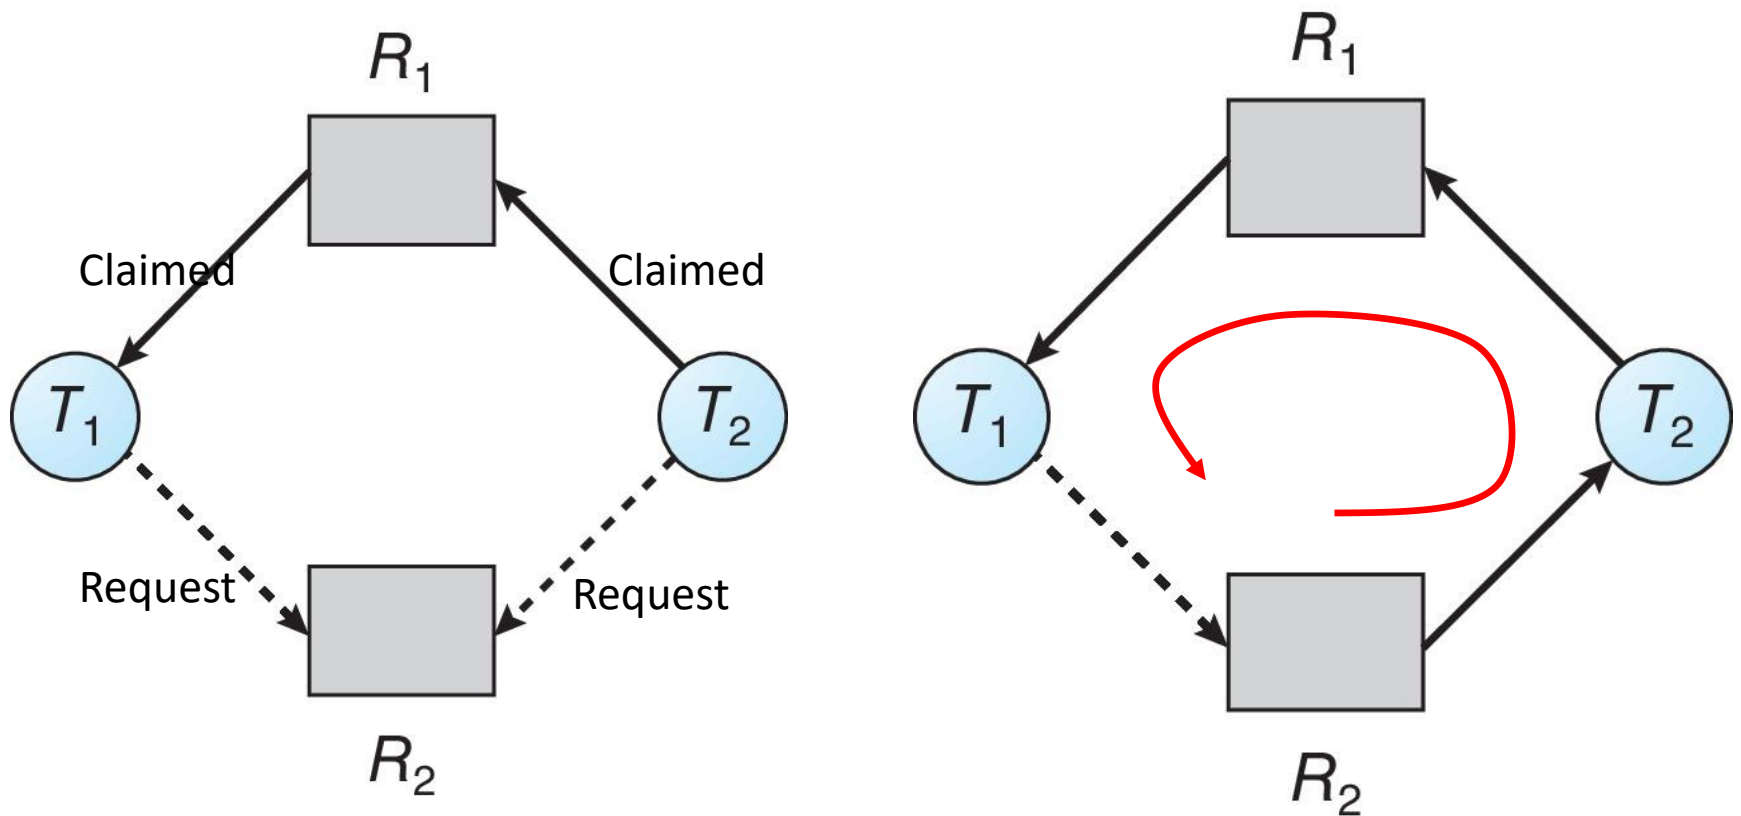

- Deadlock avoidance
  - Resource allocation
  - Resource allocation state
  - Safe and unsafe states
- When to use?
  - The resource allocation graph
  - The Banker's algorithm

# Resource-Allocation Graph Scheme

- **Claim edge**  $P_i \dashrightarrow R_j$  indicated that process  $P_i$  may request resource  $R_j$ ; represented by a dashed line
- Claim edge converts to request edge  $P_i \rightarrow R_j$  when a process requests a resource
- Request edge converted to an assignment edge  $P_i \leftarrow R_j$  when the resource is allocated to the process
- When a resource is released by a process, assignment edge reconverts to a claim edge
- Resources must be claimed *a priori* in the system

# Resource-Allocation Graph Scheme: Example

# Resource Allocation Graph

## Algorithm:

- Suppose that process  $P_i$  requests a resource  $R_j$
- The request can be granted only if converting the request edge to an assignment edge does not result in the formation of a cycle in the resource allocation graph
  - For each node in the graph if the request granted,
    - Do a depth first search, check if cycle exists
  - Complexity of the algorithm:  $O(N^2)$  (N: the number of processes)

# Questions?

- Single instance of resources
- Resource allocation graph algorithm
- Safe and unsafe state?
- How about a resource has multiple instances?

# Banker's Algorithm:

## Assumptions

- Multiple instances of resources
- Each process must *a priori* claim maximum use
- When a process requests a resource it may have to wait
- When a process gets all its resources it must return them in a finite amount of time

# Data Structures for the Banker's Algorithm

- Let  $n$  = number of processes, and  $m$  = number of resources types.
- **Available (or Free)**: Vector of length  $m$ . If available  $[j] = k$ , there are  $k$  instances of resource type  $R_j$  available
- **Max**:  $n \times m$  matrix. If  $Max [i,j] = k$ , then process  $P_i$  may request at most  $k$  instances of resource type  $R_j$
- **Allocation (or Has)**:  $n \times m$  matrix. If  $Allocation[i,j] = k$  then  $P_i$  is currently allocated  $k$  instances of  $R_j$
- **Need**:  $n \times m$  matrix. If  $Need[i,j] = k$ , then  $P_i$  may need more instances of  $R_j$  to complete its task

$$Need [i,j] = Max[i,j] - Allocation [i,j]$$

# Safety Algorithm

1. Let **Work** and **Finish** be vectors of length  $m$  and  $n$ , respectively. Initialize
  - Work = Available**
  - Finish [i] = false for  $i = 0, 1, \dots, n-1$**
2. Find an  $i$  such that both
  - (a) **Finish [i] = false**
  - (b) **Need<sub>i</sub> ≤ Work**If no such  $i$  exists, go to step 4
3. **Work = Work + Allocation<sub>i</sub>**  
**Finish[i] = true**  
go to step 2
4. If **Finish [i] == true** for all  $i$ , then the system is in a safe state

# Resource-Request Algorithm for Process $P_i$

**$Request_i$**  = request vector for process  $P_i$ . If  **$Request_i[j] = k$**  then process  $P_i$  wants  **$k$**  instances of resource type  **$R_j$**

1. If  **$Request_i \leq Need_i$** , go to step 2. Otherwise, raise error condition, since process has exceeded its maximum claim
2. If  **$Request_i \leq Available$** , go to step 3. Otherwise  $P_i$  must wait, since resources are not available
3. Pretend to allocate requested resources to  $P_i$  by modifying the state as follows:

$$Available = Available - Request_i;$$

$$Allocation_i = Allocation_i + Request_i;$$

$$Need_i = Need_i - Request_i;$$

- If safe  $\Rightarrow$  the resources are allocated to  $P_i$
- If unsafe  $\Rightarrow P_i$  must wait, and the old resource-allocation state is restored

# Banker's Algorithm for Multiple Resources

1. Look for a row in  $R$  (i.e., Need), whose unmet resource needs are all smaller than or equal to  $A$  (i.e., Available). If no such row exists, system will eventually deadlock.
2. Assume the process of row chosen requests all resources needed and finishes. Mark that process as terminated, add its resources to the  $A$  vector.
3. Repeat steps 1 and 2 until either all processes are marked terminated (safe state) or no process is left whose resource needs can be met (deadlock)

# Banker's Algorithm: Example

- 5 processes  $P_0$  through  $P_4$ ;

3 resource types:

A (10 instances), B (5 instances), and C (7 instances)

- Snapshot at time  $T_0$ :

	<u>Allocation</u>	<u>Max</u>	<u>Available</u>
	A B C	A B C	A B C
$P_0$	0 1 0	7 5 3	3 3 2
$P_1$	2 0 0	3 2 2	
$P_2$	3 0 2	9 0 2	
$P_3$	2 1 1	2 2 2	
$P_4$	0 0 2	4 3 3	

- The content of the matrix **Need** is defined to be **Max – Allocation**

	<u>Need</u>		
	A	B	C
$P_0$	7	4	3
$P_1$	1	2	2
$P_2$	6	0	0
$P_3$	0	1	1
$P_4$	4	3	1

- The system is in a safe state since the sequence  $\langle P_1, P_3, P_4, P_2, P_0 \rangle$  satisfies safety criteria

# Example: $P_1$ Request (1,0,2)

- Check that Request  $\leq$  Available (that is,  $(1,0,2) \leq (3,3,2) \Rightarrow$  true

	<u>Allocation</u>	<u>Need</u>	<u>Available</u>
	A B C	A B C	A B C
$P_0$	0 1 0	7 4 3	2 3 0
$P_1$	3 0 2	0 2 0	
$P_2$	3 0 2	6 0 0	
$P_3$	2 1 1	0 1 1	
$P_4$	0 0 2	4 3 1	

- Executing safety algorithm shows that sequence  $\langle P_1, P_3, P_4, P_0, P_2 \rangle$  satisfies safety requirement
- Can request for (3,3,0) by  $P_4$  be granted?
- Can request for (0,2,0) by  $P_0$  be granted?

# Questions?

- When to use the Banker's algorithm?
- Data structures?
- Algorithm?
